## THE LBNL QUANTUM EFFICIENCY MACHINE

or: What can we do with a large dark box?

Don Groom, C. J. Bebek, M. Fabricius, J. A. Fairfield, A. Karcher, W.F. Kolbe, N. A. Roe, & J. Steckert

- Light from the Xe arc lamp goes through two filter wheels, which pass selected 150 nm bandpasses. The light is
- dispersed by the MS257 monochromator, and then forms a spot on the wall of the integrating sphere.
- The homogenized light from the sphere exits through a 4-inch port at right angles to the incoming light.
- It illuminates the exit port of a dark box about 1 m from the integrating sphere exit port.
- The CCD and a calibrated reference photodiode are inside the dewar (shown below) attached to the dark box.

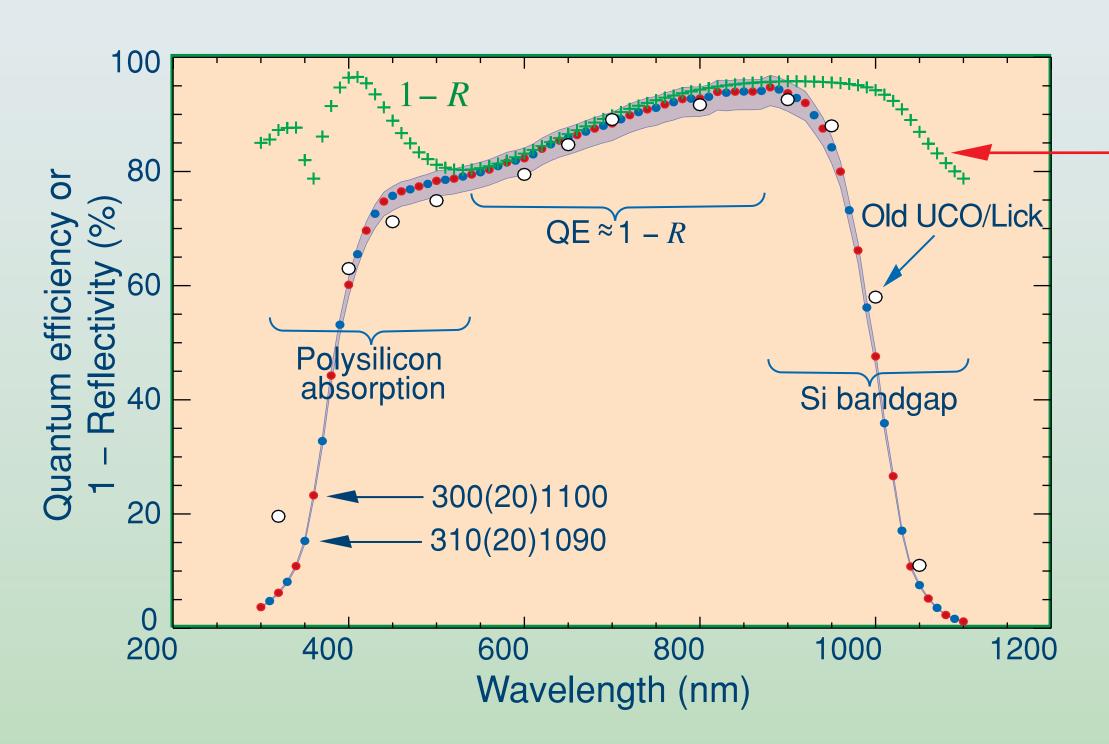

Black box Dewar  $(31" \times 24")$ **Monoch**romator Optical fiber Lamp Housing  $150 \text{ cm} \times 90 \text{ cm}$ Filter Wheels CCD @ -140° C and Shutter Calibrated standard PD, coplaner with the CCD and on its own heat sink, at 25° C. QE MACHINE This arrangement eliminates corrections for VERSION 3.0 window reflections, geometry, and light intensity variations with time.  $180 \text{ cm} \times 90 \text{ cm}$ 

## Measure CCD quantum efficiency

This is the primary function of the QE Machine.

"Typical QE scan" of a proto-SNAP CCD. Red dots mark 10 nm bands scanned upward by 20 nm steps; blue marks an interleafed downward scan. In part, this serves as a stability check.

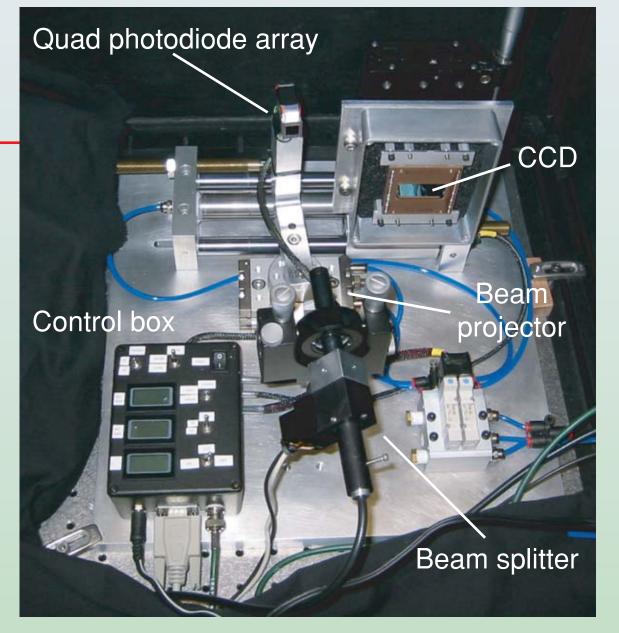

Reflectivity measurement on the same CCD, plotted as 1-R

#### Measure reflectivity

We consider measurement of reflectivity (R) to be a necessary part of a QE determination:

 $1-R \ge QE$  everywhere, and 1-R = QE in the broad central region where the internal QE is essentially unity It is an invaluable "sanity check." In addition to a variety of beartraps in direct methods,

ALL OF THEM INVOLVE BLIND FAITH IN THE REFERENCE PHOTODIODE CALIBRATION

### Calibration:

Problem is to find the number of ADU counts associated with one electron.

 Traditionally, calibrated with the 5.90 keV K-alpha Mn x ray associated with <sup>55</sup>Fe decay. But conversion from eV to ADU is temperature-dependent.

Or use the "fast photon transfer method." The photon transfer method uses the fact that if there are (n) electrons per pixel, the fractional variance is 1/(n). The "fast photon transfer method" is a tricky way to do it in one exposure.

# Measure quantum efficiency of CCD

(wired as a CCD, any temperature) The CCD's reset MOSFET is connected to the serial register, and the photocurrent is

total depletion. Currents in the CCD cum PD and the QE PD-mode, room temperature calibrated photodiode are measured; their QE PD-mode cold (-140° C) ratio, with area corrections, is essentially the QE ratio. QE CCD-mode cold --

Wavelength scans are made as in the CCD mode measurements.

#### The "Spot-o-Matic" spot projector

A long focal-length microscope objective is used to focus light from an optical fiber (not shown) from the monochromator axial port onto the CCD. The beam size (rms) is  $1.3 \pm 0.1 \, \mu m$ .

Define a fiducial region which can totally contain the projected spot. Scan across until the spot is totally outside the region. The profile maps the integral of one projection of the point-spread
